REVIEW

A Detailed Structural Review of Onshore and Offshore Pipelines Containing Defects

Frederick Ebili ^{1,2} , Selda Oterkus ¹* , Erkan Oterkus ¹

ABSTRACT

This study presents a thorough and holistic review of various studies focusing on the structural analysis of Oil and Gas (O&G) pipelines, with an emphasis on various defect modes. The study appraised pipeline-related articles from the empirical, semi-empirical, analytical, and numerical studies. However, the study's core objective remains to address the persistent challenge that often leads to Burst Pressure Loss (BPL) in a pipeline. These mechanical-associated damages, which can result in BPL, may include pipe scratches, dents, or cracks. Therefore, training a large volume of datasets in neural network architectures or the finite element domain is crucial in this context. The study further explores previous research to gain a deeper insight into how many modes of damage enhance loss in Burst Pressure (BP). The study further synthesises significant reasons why pipeline Structural Health Failures (SHFs) occur, as drawn from existing literature. Failure scenarios in pipeline dent, crack, fracture, buckling, fatigue, corrosion, BPL, and Third-Party Damage (TPD) could result from mechanical deformation, ageing, insufficient real-time monitoring, and TPD influences. Many of the assessed articles conclude that the

experimental approach and Finite Element Method (FEM) are valid and can accurately validate one another in the analysis and prediction of pipeline failures. However, this study offers valuable and comprehensive resources for pipeline engineers, academic researchers, and industry professionals. Again, the study is crucial for pipeline fabricators, installers, and operators to keep up with maintenance, repairs, and predictions.

Keywords: Oil and Gas (O&G); Onshore and Offshore Pipelines; SHFs; FEM; BPL; Several Failure Modes

1. Introduction

The operational pipeline system for both onshore and offshore oil and natural gas has long been recognised as the most efficient, effective, economical, and safest method for energy transport. The above assertion is supported by numerous scholarly research articles [1-5]. Notably, the long decade of significant shift from oil to natural gas has triggered an increase in pipeline construction and installation worldwide [6]. This change has attracted greater attention from the Oil and Gas (0&G) industry, academic sector, and research institutions. From a practical and traditional perspective, API 5L X42-120 seamless grade carbon steel pipelines are considered more suitable and efficient for transporting this energy. The longitudinal Seam Submerged Arc Welded (LSSAW) is the closest alternative to API 5L X42-120 seamless pipelines; however, there is no comparison between the two grades of pipeline.

A dearth in numerically and remotely real-life monitoring and prediction programmes for operational pipelines has inspired this study. The research gap in computationally and artificially trained datasets in this regard is a great concern. This acute problem in the 0&G sector demands urgent attention as we prepare for alternative energy through carbon emission reduction and a new energy source by 2050. Solving this problem would have reduced emissions due to catastrophic events upon explosion. Therefore, harnessing datasets of pipeline scratches, micro-dents, and cracks can collectively or individually address the persistent pipeline BPL and its accurate prediction. To accurately enhance the prediction of BPL damage in isotropic carbon steel oil and natural gas pipelines, it is vital to gather extensive and detailed field datasets. Training these datasets is therefore necessary. Employing advanced Neural Network Architectures (NNAs) and Finite Element Analysis (FEA) is aimed at refining Burst Pressure Loss (BPL) calculations and predictions of pipeline behaviour.

Several significant challenges, however, should be addressed throughout this process. These include strict time constraints that can limit both data collection and analysis. The availability of essential resources, such as equipment and skilled personnel, and complex bureaucratic procedures that differ from country to country, can impede swift project implementation. Furthermore, challenges related to right-of-way permissions may complicate access to pipeline locations, ultimately impacting the speed and effectiveness of data gathering efforts. Overcoming these obstacles is crucial through the successful utilisation of NNAs or alternative software in the vital field of pipeline integrity studies.

The study aligns with the recent research conducted by Chen et al. [7] on the use of artificial intelligence for monitoring onshore TPD pipelines. As such, it serves as a framework for addressing the issues previously discussed. Consequently, the study introduces a novel approach for predicting BPL defects in pipelines, through some damage modes of failure detailed in the following tables. This information will also provide a foundational basis for enhancing future calculations and predictions of pipeline BPL.

1.1.Brief History of Carbon Steel Pipeline Design and Installation

Pipeline defects are of great concern as they threaten the safety of oil and natural gas transport across the globe ^[8,9]. A China Daily newspaper reported how hollow bamboo plants were used in transporting the first encountered brine while mining for salt in Sichuan province centuries ago (220 BC) ^[10,11]. Vogel's ^[12] research study validated the brine transport in bamboo tubes in China about 2000 years ago. Moreover, the first-ever water piping network used the same hollow bamboo plants ^[10,11]. At the brine mining station for

salt refinement, the transported natural gas encountered from the brine well to the surface was the same array of bamboo tubes [13]. Again, the first-ever carbon steel pipeline for natural gas transport was used in Fredonia, New York, United States of America, in 1821. Between the 1930s and 1970s, carbon steel pipeline installation for oil and natural gas transport grew and revolutionised the world. The pipeline defects review contained here is a synopsis of oil and natural gas pipelines, fundamental approaches to structural defect analysis, remediation, structural integrity, and simulations for prediction as evaluated from various previous articles. The information about the empirical, numerical, analytical, and other approaches used for pipeline defect resolutions is well explored, demonstrated, and utilised.

1.2.Onshore and Offshore Oil and Natural Gas Pipeline Overview

Carbon steel and composite pipeline technological design have faced structural challenges globally. These challenges are, however, felt in structural analysis, which has confronted pipeline integrity over the years. Nevertheless, an efficiency optimisation analysis and structural stability prediction are always in view to benchmark cutting-edge pipeline designs [9,14,15]. BPL, crack growth, and corrosion fatigue are some of the structural challenges that have bedevilled pipelines in operation over the years [16-18]. Hence, they are essential parameters for investigating and analysing O&G pipeline integrity globally.

However, these essential parameters are vigorously synchronised using some of the best approaches from the cited literature to validate experimental procedures with numerical or computational models. Maintaining standard operational practice and safety procedures in a pipeline is critical to maximise flow. Flow obstructions due to defects have required structural assessment and operational control to optimise pipeline functionality and integrity. This study extensively summarises different defect modes and those parameters that ensure pipeline safety to maximise energy profit across the O&G sector globally [8,19,20].

and Wang [20], Zhang and Zhou [23], and Ghavamian et al. [8], have proved that corrosion poses the most endemic and catastrophic threat to the operational integrity of natural gas pipelines. In this context, internal corrosion is identified as the primary cause of subsea pipeline failure. Usually, it leads to an attrition in pipeline thickness that can ultimately result in Stress Corrosion Cracking (SCC) and a loss of internal Burst Pressure (BP). In contrast, the research of Durowoju et al. [24] expressed different opinions regarding pipeline damage in a more general context. Their opinion suggested that Third-Party Damages (TPDs) and installation challenges are the primary factors contributing to pipeline failures. Again, Durowoju et al. [24] pointed out that most TPDs are due to anthropogenic influences occurring along the first 180° part of the buried pipeline near the surface. The 180° exposed part of the pipeline to the pseudo intender, which can cause a dent in a pipeline and potentially initiate a micro crack in some cases. However, concurrent Static Burst Pressure (SBP) analysis is another mode of damage that employs slightly different shear stress failure criteria for corrosion defect evaluation [25]. Notably, the dent impact on a pipeline may lead to other damage modes if prompt repair action is not deployed to fix the operational pipeline. Alexander et al. [26] have uncovered dent behaviour in a pipeline and tagged it as mechanical damage caused by a Third Party (TP). Such damage can lead to additional damage throughout the pipeline's service life. This damage drops the fatigue life and becomes more severe with an increase in the dent at the cause of the service pipeline lifecycle.

The whole idea of pipeline specification before design and construction is optimal to withstand the proposed environmental conditions of application. The environmental conditions may be harsh marine environments, external loading conditions, and several operational conditions that challenge structural integrity and safety. The Finite Element Method (FEM) has emerged as a powerful computational technique for analysing the operational behaviour of pipelines under various loading conditions. This study provides a comprehensive overview of the FEM application and Several authors, including Nešić [21], Race [22], Tse analysis of pipelines, focusing on modelling techniques,

material behaviours, environmental loading conditions, and failure mechanisms. Insightfully, various case studies are assessed in detail in this study to highlight the effectiveness and challenges associated with computational FEM and empirical formulation in the context of pipelines' O&G transport systems.

2. Structural Advantages of FEM and its Application in O&G Pipeline Analysis

The FEM has proven to be highly effective for structural analyses over the years, making it a recommended approach for solving boundary value problems in engineering structures. Most of the research work reviewed in this study employed FEM for comprehensive structural analysis, validating various analytical, experimental, or semi-empirical approaches, as cited in several articles included in this structural review. For instance, Shahid et al. [27] demonstrated the capabilities of FEM in analysing fibre-reinforced polymer (FRP) sleeves used for repairing subsea carbon steel pipelines under different operating conditions. As a simulation technique, FEM can numerically assess the physical and mechanical properties of a pipeline composite material, particularly its resistance to corrosion and mechanical damage [1,28,29]. The efficiency and reliability of FRP extend beyond repairing isotropic carbon steel pipelines. They are also crucial in the fabrication and construction of flanges to enhance integrity in the operational phase of the pipeline lifecycle [30]. Furthermore, the failure pressure calculations provided by pipeline specification agencies such as American Society of Mechanical Engineers (ASME) B31G, Det Norske Veritas (DNV), and Predictive Corroded Pipe Rupture Criteria (PCORRC) can validate the results obtained from FEM analysis from the literature assessed.

Pipeline Operation and Structural Defects

The operational phase of the O&G pipeline is crucial, as it significantly impacts the stability and integrity of the pipeline during its lifecycle. However, conducting routine checks during operation enhances structural integrity. Structural damages may arise from environ-

mental factors, Maximum Allowable Operating Pressure (MAOP), natural frequency of pipe, and the pipeline's service life challenge. Witek [31] conducted a structural integrity investigation focused on a buried onshore natural gas pipeline, specifically evaluating defects associated with natural phenomena and the ageing of pipelines. Surface corrosion defect in this scenario was the common defect analysed [31]. Structural defects represent tough challenges in maintaining robust infrastructures, including pipelines. Therefore, adhering to structural regulations and operational protection protocols is vital for ensuring safety. Cosham and Hopkins [32] provided several recommendations after assessing various structural defects in pipelines by validating the Standard Operating Procedure (SOP) outlined in ASME B31G, Remaining Strength (RSTRENG) of corroded pipe, American Petroleum Institute (API), and related guidelines. Furthermore, their pipeline defect appraisal document offered valuable insights for preventing and controlling defects in O&G pipeline operations, applicable to both onshore and offshore environments. Witek [31] emphasised the need for regular inspections and maintenance to manage structural defects and prevent potentially catastrophic damage to pipelines.

3. Review Methodology and Applications

A systematic review methodology has been established for this structural review, enabling the study to effectively analyse literature based on structural parameters and arguments presented in each reviewed article. The idea of data extraction and synthesis from previous literature is to ensure thorough analysis, evaluation, and documentation throughout the review process. The purpose of this information is to address structural research inputs and gaps. The graphical representation of O&G pipeline publications in **Figure 1** portrays article tracking and harmonisation over the years. Of course, **Figure 1** clearly illustrates the collected literature publications with fluctuations over the past five and a half decades. The sharp exponential jump between 2007 and 2010 in **Figure 1** significantly addresses the period of the energy production and transportation boom

between 2010 and 2018, for about a decade, could have resulted from the alternative energy decision stage. The decline in publications in the literature between 2017 and 2020 reflects the net-zero carbon emission phase (**Figure 1**). The increasing momentum aimed at achieving net-zero carbon emissions by 2050 may be

However, the steady and consistent publication period responsible for the significant decline in gas pipeline publications in the literature. However, as the transition to alternative green energy progresses, publications related to the net-zero carbon agenda are expected to rise geometrically between 2030 and 2050. A key issue in this transition is the decommissioning process of old pipelines.

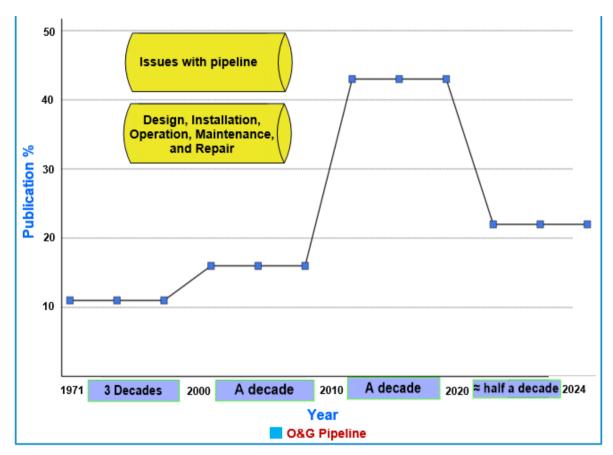

Figure 1. 0&G pipeline structural publication distribution for over five and half decades.

best methods for transporting new energy and the maintenance process of existing energy sources. The rehabilitation of existing pipelines for alternative green energy, as well as the construction and installation of new green energy pipelines, is frequently highlighted in many sustainable marine and energy journals [33-37]. Consequently, there is a rapid growth in the development of new materials designed to enhance carbon steel pipelines with advanced composite structural materials suitable for alternative green energy. Moreover, repurposing existing pipelines for alternative energy could present promising research assessment of existing related articles.

This topic raises crucial discussions about the opportunities in the future. This review study focuses on the existing literature surrounding the structural analysis of carbon steel pipeline publications. A good example is the Lancaster and Palmer's [38] pipeline structural analysis of dent and gouge combination for BPL influence.

> The yearly publication distributions, as presented in Figure 1, clearly demonstrate the trend in the quantity of literature in this field of study. The publication in percentage (%) of the Y-axis gives information on the number of publications in % over the years on the X-axis. This information assisted in the collection and

3.1.Datasets Application for Pipeline BPL **Prediction**

To significantly improve BPL damage predictions in pipelines, it is essential to account for mechanical damage modes like scratches, dents, and cracks. Collecting datasets before and after installation is critical to this process. Moreover, employing advanced remote sensing technology, such as wireless ultrasonic and sunspot sensors, provides a reliable and efficient way to gather this vital data. By prioritising these practices, pipeline safety and performance are enhanced.

- Datasets can systematically serve as the foundation for training a machine learning model. Equipment for data collection, such as Shogun, a real-time monitoring remote sensor, is possible for this assignment. This data should encompass various scenarios of a particular damage mode. An example is a scratch or dent to ensure comprehensive learning.
- Pre-processing involves cleaning to remove inaccuracies, handling missing values, and standardising the formats. Additionally, transforming the data into a more suitable structure or representation, such as normalising numerical values or encoding categorical variables, allows for preparing it effectively for model training.
- Training Process involves the utilisation of the cleaned and pre-processed datasets through a machine learning algorithm that aligns best with the specific objectives of the task. During this phase, the model could draw on historical data, thereby adjusting its internal parameters to minimise errors and improve its predictive performance. This process may involve multiple iterations based on the feedback from the model's initial performance.
- **Predictions** are possible with an adequately trained model. However, numerically, predictive models can be implemented and used to validate subsequent research results. This application enables the model to demonstrate its ability to generalise from past examples and make informed decisions.
- of the whole process. A rigorous assessment of the while the yellow captions are examples of the opera-

model's performance using an appropriate computational tool, such as FEA in ANSYS, FEA in ABAQUS, and Workbench Optimisation Domain, depending on the task objective. Based on this evaluation, an optimisation programme is necessary in this regard. It may include fine-tuning parameters involved and employing advanced techniques, such as cross-validation, or retraining with additional data to enhance performance and accuracy.

3.2.Different Failure Modes of Onshore and **Offshore Pipelines**

Real-time investigations of pipelines in operation and those that have suffered a catastrophic event, such as explosions caused by BPL, require critical insights into data collection and analysis. Over the years, researchers have explored this area by examining various structural defects in pipelines. However, for more accurate and detailed analysis and predictions, particularly regarding BPL, training large datasets and FE analysis are essential. The reviewed literature has utilised software simulation tools to predict potential future damages in pipelines. The study not only connects these various structural investigations but also seeks to bridge the existing gaps in the study domain, considering this study's aim and objectives.

Figure 2 is a schematic representation of possible generic onshore oil and natural gas defects, starting from human external interference, design/mechanical, operational lifecycle, and natural disasters that could result in pipeline failure. The cylindrical pipeline damage representation includes different colour captions. The anthropogenic activities (external interferences) on onshore O&G pipelines are considered TPDs. The TPD in Figure 2 is the first captioned in the red cylinder. The TPDs' influence on the onshore pipeline encompasses land excavation for new projects, drilling, theft, and heavy-duty truck vibration, which are all capable of causing pipeline damage. The brown captions are for the pipeline damage modes associated with mechanical • Optimisation is the final phase after the deployment impacts during pipeline transportation and installation, natural disasters.

The damages in subsea pipelines share a similar fate to those onshore during installation and operation. However, there are notable differences in the types of TPDs and the natural disasters, which have the potential to destroy the pipeline. For subsea pipelines, TPDs include anchor drops, heavy object impacts (rockfall), trawling gear, and ships running aground. The natural disasters affecting subsea pipelines encompass tectonic eruptions, strong sea currents, tsunamis, earthquakes, and many more.

Johnson and Vigilante [39] clarify this issue by referencing findings from the Pipeline and Hazardous Materials Safety Administration (PHMSA) and the European Gas Pipeline Incident Data Group (EGIG). Their findings indicate that TPDs and corrosion are the primary causes of pipeline damage and failures. In the context of natural gas pipelines in the USA, welded joints, par-

tional phase in the pipeline. The blue caption indicates ticularly in the butt weld sections of pipes, are identified as the most common type of defect. Guedes and Caro [40] further emphasise that external interference, whether onshore or offshore, ranks as the second leading cause of failures, following corrosion. For a comprehensive overview of TPDs, refer to the Handbook of Pipeline Engineering by de França Freire et al. [41]. Figure 3 schematic portrays information about subsea 0&G pipeline challenges. The damage types are in an array of dwarf-coloured cylinders that represent different damage modes of the subsea pipeline. The yellow arrow pointer indicates the TPDs, and the overlapping yellow rectangular boxes with the light green dwarf cylinder indicate design/mechanical damage. Again, the light blue cylinders represent operational/lifecycle problems, while the deep blue cylinder depicts natural disasters. Other than the TPDs and natural disasters, the design/mechanical and operational/lifecycle problems remain the same with the onshore pipelines.

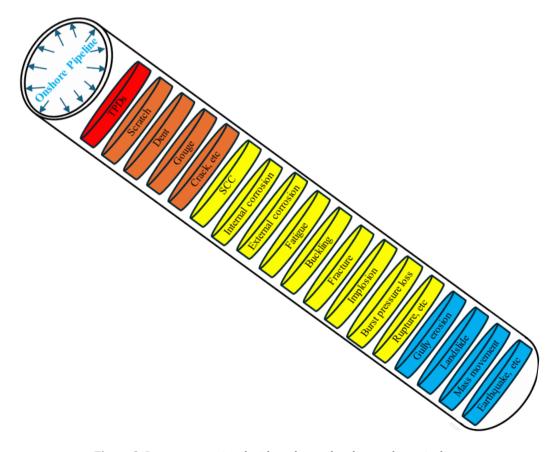

Figure 2. Damages associated with onshore oil and natural gas pipeline.

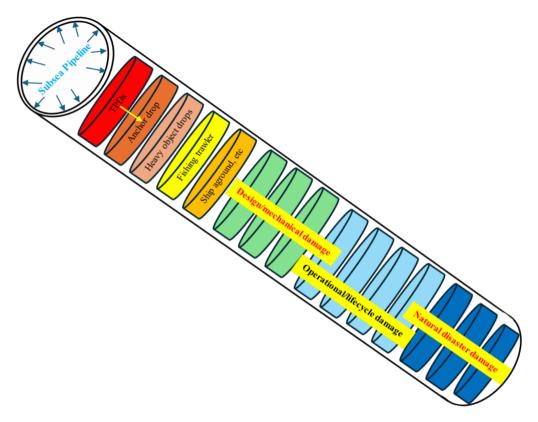

Figure 3. A special schematic of possible defects to the subsea O&G pipeline.

3.3.Indentation

Dent formation in a pipeline has consistently posed a difficult challenge to onshore and offshore oil and natural gas pipelines. This damage mode, however, is an inevitable defect during the pipeline fabrication and installation process, and very often it degenerates into a BPL challenge after micro-crack initiation. Micro-dents and micro-crack data mining, however, is one of the best pieces of information for studying damage like BPL in a pipeline. Pipeline standardisation and specification manuals offer more information to caution pipeline engineers and operators. The pipeline manual also helps with decision-making during pipe procurement for energy transport. In the same vein, dent evaluation and depth acceptability levels are further investigated by Wu et al. [42]. Note that a dent in the pipeline compromises BP resistance, collapse, and local buckling resistance in operation. Additionally, experimental and numerical investigations by Zeinoddini et al. [14] prove that the reduction in BP increases the risk of pipeline failure. This risk could result from elevated internal pressure due to the combination of dents. Following tables present an in-depth analysis and comparison of various onshore and offshore pipeline failure modes. Differences in pipeline structural defects from appraised articles based on empirical, semi-empirical, analytical, and numerical analyses reveal previous pipeline failures and possible solutions. The study introduces a new perspective, the possibility of utilising a trained dataset from pipe scratches or dents for FE simulation of BPL damage prediction. It highlights the significance of the pipeline operational environment and emphasises the need to consider different pipeline grades. The simple reason for multiple grades of pipeline is to generate more data for adequate training and analysis to improve safety and efficiency in pipeline operation. Persistent BPL drives this idea for this innovative study.

Figure 4 schematic portrays a pseudo-indenter used for creating a deep dent on the surface of an off-shore pipeline structure. The pipe thickness remains unchanged even at the indentation spot. However, the indenter causes a deep depression, which in turn creates a high stress concentration. Such indentation may lead to several other damages around the dent region. The dent could initiate a micro-crack due to high-stress

field concentration within the dent environment, due practical indentation examples. However, to ensure opto flow pressure inside the pipeline. Residual stresses around the dent's internal and external surfaces are the differences between a possible observed stress value and the predicted value. According to Hyde et al. [43], Other pipeline damage problems, like fatigue in an operational gas pipeline, were investigated using the

erational stability in O&G pipelines, there should be a routine Structural Health Monitoring (SHM) as set by industrial pipeline experts [1]. Consequently, the structural integrity of pipelines should be a top priority for operators to ensure stability, as this study demon-

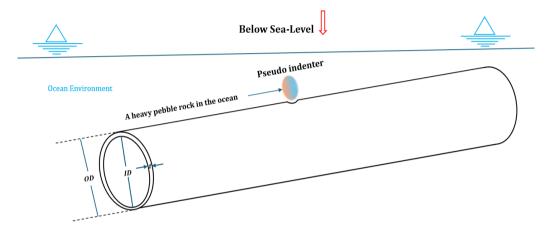

Figure 4. A schematic view of practical example of indentation possibility in the offshore environment.

3.4.Crack Initiation and Propagation in a **Pipeline**

Simulation methods for structural analyses are profoundly and exponentially advancing with technological improvement to stabilise the health of marine structures, especially the O&G pipelines. The FEM for crack investigation is mostly cross validated using empirical results to optimise the structural analysis of different models used in discussing various structural parame-

ters in this study. **Figure 5** further illustrates the study of Valadi et al. [44] on the strength of the eXtended Finite Element Method (XFEM) for crack investigation. Most 0&G pipeline crack problems could occur due to pipeline stress-related loading, which is known as material Sulphide Stress Cracking (SSC). However, crack repair in the pipeline is possible as illustrated in **Figure 6**. The composite reinforced sleeve is a good material for wrapping pipelines during crack repair, as well as pipe joining.

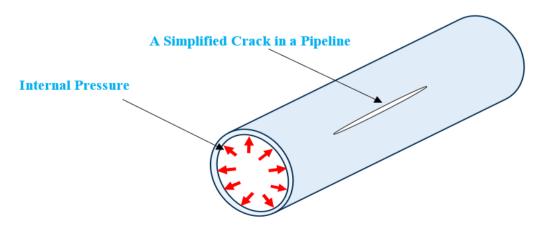

Figure 5. A pipe with simplified crack defect under internal pressure.

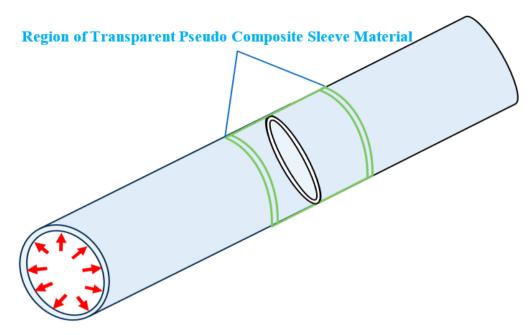

Figure 6. Schematic of imaginary composite sleeve materials for possible joining or repairing of cracked pipeline.

The Finite Element (FE) numerical approach can effectively identify micro-cracks in pipelines, which often degenerate into crack propagation through element paths instead of node grid paths of the model [44]. However, cracks can also propagate through node grids depending on their orientation. The limitations of Classical Continuum Mechanics (CCM) and the foundation of traditional FEM are, however, addressed by the XFEM. Nevertheless, the propagation challenge persists in visualising the portion of the element that is affected once the crack loses its continuity. Thus, the capabilities of CCM remain relevant within the context of XFEM. In Figure 5, the red arrows indicate internal pressure, which often poses a potential threat to an already cracked pipeline, whether from internal or external surfaces of the pipe.

A powerful and robust approach, known as the peridynamic (PD) theory, has been developed to effectively address the limitations of XFEM and CCM in crack problems. This innovative approach, called PD, was first proposed by esteemed scientist Stewart A. Silling, who aimed to find solutions to the aforementioned challenges in crack propagation. PD focuses on managing crack-related damages in solid mechanics and beyond. Numerous studies have explored this area, including

Kilic and Madenci ^[45,46], Silling and Lehoucq ^[47], Oterkus and Madenci ^[48], and Madenci and Oterkus ^[49], among others.

Additionally, Candas et al. ^[50], Shi et al. ^[51], and Candas et al. ^[52] have carefully demonstrated the effectiveness and efficiency of PD for structural analysis. Their findings highlight the structural capacity of PD for material advancement and development based on the following:

- Micro-crack identification and propagation envision under a sudden and transient force of application on Functionally Graded Materials (FGMs) [50].
- Analysis of SCC on carbon steel pipeline materials based on initial crack stage formation and propagation resulting from mechanical agitation and corrosion effect [51].
- Investigation of dynamic fracture in FGMs to understand optimal variation and formulation pattern of material property [52].

In the same line of idea is the innovative contribution of Imachi et al. ^[53] on dynamic crack propagation. Conclusively, the PD approaches appraised for crack investigations demonstrate that both non-ordinary and ordinary state-based, along with bond-based methods,

are numerically feasible within the PD crack analysis framework. The above structural studies are potentially possible for O&G carbon steel pipelines to improve stability and integrity.

3.5.Buckling-Collapse Failure in Pipelines

Buckling in pipeline structure is one of the critical and challenging damage modes of a pipeline, which often results from overloading of a structure or design errors, like dents or ovalisation in a pipeline [54,55]. This sudden mechanical deformation occurs from the axial compression load, and it is only when the compressive load on the pipeline reaches a critical value. According to Kyriakides and Corona's study [55], an experimental approach can predict pipeline buckling under a high bending pressure load (external force) at the installation stage of the pipeline. On the other hand, the collapse behaviour of pipelines under bending and axial loads is primarily caused by a dent in the pipeline. Both problems could result in catastrophic failure and create a highly undesired scenario within a specific region of the pipeline location. These two damage modes are discussed further in following tables along with other damage types.

The buckling of a pipeline due to external pressure, thermal expansion, or lateral loads is discussed extensively by Sun et al. [56], Wang et al. [57], and Cai and Grognec [58]. The FEM serves as a certified approach for predicting critical buckling modes, such as global buckling or local buckling occurring at welds or supports of a pipeline. Additionally, Gong et al. [59] highlighted that buckling occurs due to various types of loading, including axial tension, bending moments, and external loading regimes. Collapse failures in subsea oil and natural gas pipelines could be due to external pressures, such as hydrodynamic loads. Gong et al. [59] predicted that the ability to withstand extreme external pressure loading conditions revolves around compliance with design safety standards and installation rules with operational limits in a pipeline. In this scenario, an imperfection in the cylindrical shape of a pipeline can be a potential buckling threat in the operational pipeline. defect types are written boldly across all tables.

Gong et al. [59] reiterated these imperfections in pipe design geometry to predict possible failure in an operational pipeline. Additionally, Dadfar et al. [54] and Gong et al. [59] provided separate simple approaches to practically aid in minimising this imperfection during design and fabrication. Kyriakides and Corona [55] stated that a micro-wrinkled pipeline could lead to buckling challenges and potential failure in existing onshore or offshore operational O&G pipelines. In the O&G sector, most radiographic testing of pipelines for wrinkles may also go through a Scanning Electron Microscope (SEM) to certify it for installation and commissioning for operation deployment.

The Tables 1-4 framework is structured based on one of the study's core objectives, which was to systematically filter and summarise all necessary information from each appraised literature. Each table header and sub-header thematically portrays the general structural review pattern. The detailed appraised literature in Tables 1-4 presents various structural problems associated with pipelines, such as dent, crack, buckling, fracture, fatigue, stress, and TPD. Again, Tables 1-4 summarise the overview of several studies on defect pipelines. An example is the detailed study of Xu et al. [60] expressing different corrosion predictive models in **Table 2**. Xu et al. [60] listed predictive models, such as Back Propagation Neural Network (BPNN), Complete Ensemble Empirical Mode Decomposition with Adaptive Noise (CEEMDAN), Genetic Algorithm (GA), Improved Particle Swarm Optimisation (IPSO), Particle Swarm Optimisation (PSO), and Support Vector Machine (SVM). Among the structural defects appraised in Tables 1-4, pipeline corrosion damage is imminent, especially for offshore pipelines. Table 2 presents an assessment of corrosion damage and corrosion reduction tests, with a higher number of damage modes compared to others. The buckling, TPD, and general damage are all listed in Table 4. The grouping is for no specific reason, but with the idea of simplifying the assessed pipeline damage modes. All assessed pipeline

General pipeline assessment |

4. Review Results and Discussion

The results and discussion section of the review study is structured based on a comprehensive analysis

that integrates the empirical, numerical, and analytical methods used in all the appraised literature. The study's general structural framework was derived from the configurations and methodologies of the reviewed

articles, as reflected in the overall assessment patterns (**Tables 1–4**). These tables present and emphasise various structural implications of an undesired condition in operational O&G pipelines. Notably, some of the most common and inevitable defects in O&G pipelines are scratches, dents, and cracks, which are often indications to enhance BPL in a pipeline.

4.1.Pipeline Integrity Analysis Based on Past Failure Incidents

Subsea pipelines primarily face the risk of internal corrosion in operation, making it a leading cause of offshore pipeline failure. In the same context, the research conducted by Cheng and Chen [94] highlights the external risks faced by subsea pipelines due to hydrodynamic pressure, which can lead to external corrosion fatigue. In this regard, the assessment of pipeline structural integrity focuses on both corrosion and fatigue. In contrast, onshore pipelines are more vulnerable to external factors arising from various third-party (TP) activities, predominantly resulting from human-induced mechanical damage. On the other hand, the damage to subsea pipelines from TP activities typically occurs due to incidents such as ships running aground, dropped anchors, heavy objects falling from vessels, and fishing trawlers.

4.2.Statistics and Probability Assessment of Pipeline Internal Corrosion

Soomro et al. [4] argued that the Bayesian network approach is the most promising method for assessing the impact of internal corrosion damage on the structural integrity of O&G pipelines. Their review also listed some fascinating methods from other researchers, such as Witek [29], Cavalieri et al. [95], Zakikhani et al. [96], and Khan et al. [97]. Many researchers projected how the structural integrity assessment, the BPL, the fault identification, and the ILI models are used for pipeline failure prediction [4]. The Bayesian network stands out for its integrity and risk prediction in the context of corrosion damage of operating pipelines. Guo et al.'s [3] TPD risk assessment using the Bayesian network is another validated work by Soomro et al. [4] and Zakikhani et al. [96]. They have a general experimental setup for pipeline

data collection and analysis. Chen et al. [7] itemise the possible onshore pipeline failure influences and initiate how an AI monitoring system can ameliorate the problem due to TPD.

4.3.The Use of Corrosion Reduction to Determine Pipeline Internal BPL

Conventionally, Tse and Wang [20] have noted that corrosion is a prevalent issue in Hong Kong's pipeline system due to extreme environmental conditions. One of the damages related to hydrogen pipeline issues is embrittlement. The concept of mixing hydrogen with natural gas in the same transmission pipeline raises concerns, as introducing hydrogen could lead to a loss of toughness and increased embrittlement. While corrosion in pipelines is a global problem, different types of corrosion are tied to specific environments and tend to be more severe in certain regions, as highlighted by Nešić [21] and Ghavamian et al. [8]. For example, in Hong Kong, environmental factors significantly affect the rate of corrosion damage, particularly concerning external corrosion in buried or surface pipelines [20]. Measuring the depth of internal corrosion in natural gas or oil pipelines is essential for determining the internal BP of transmission pipelines. In this study, we explored the potential of using datasets related to pipeline scratches, dents, or cracks to train models and simulate predictions for BP. Notably, conventional methods for calculating BP include experimental, numerical, and real-world assessments. With the help of advanced machine-aided field evaluations, laboratory setups, and computational software, predicting BP has become more manageable, as demonstrated in some sections of Table 3. A notable example is the work of Fahed et al. [98], who conducted experimental and FEM to evaluate the internal BP of corroded API X42, X52, and X70 grade pipes. Su et al. [18] utilise the retained BP of a pipeline as a specific parameter to calculate the remaining strength of corroded steel pipeline structures, which is another method. Nevertheless, the corrosion challenge of steel pipes' grades X42 to X120 could reduce pipe internal pressure, which is an inescapable condition during operation [17,18].

validated work by Soomro et al. [4] and Zakikhani et al. However, Song et al. [74] used various masses of Trinitrotoluene (TNT) as an explosive to blast pipe-

lines of different thicknesses at varying time intervals (in microseconds) to study their BPL capacity. Song et al. [74] also confirmed that the pipe blasting technique to determine the internal BP of a pipe is in contrast to the effect of corrosion as an environmental factor. O&G pipelines are often installed in harsh environments, far from urban or inhabited areas within their operational environment. Hence, they are susceptible to environmental attacks like corrosion and hydrostatic pressure. Thus, continuous advancement in pipeline design and the use of corrosion-resistant material becomes imperative. Oin et al. [17] discussed the internal pressure retained in a pipeline after experiencing corrosion effects on high-grade steel (X100) as the remaining strength of the pipeline. The Near-Neutral Simulation with pH-4 (NS4) is a chemical solution that is slightly acidic, with a pH close to 7. The NS4 solution is assumed to have corroded the steel pipe in the experimental setup by Qin et al. [17]. The simulated corrosion effect, however, is in a localised form, which can manifest as pitting, filiform, or crevice corrosion in real-life scenarios. Figure 7 depicts a random and irregular pipe pitting corrosion pattern in a long-distance hydrocarbon carrier. The rougher and sharper the corrosion on the X100 steel grade used, the greater the localised stress distribution in that region. Pluvinage et al. [93] used a simple equation to suggest that plastic collapse system analysis can predict BP damage. For example, if a pipe incurs a corrosion crater or experiences spallation due to corrosion, the following **Equation (1)** is possible.

$$\frac{\partial P}{\partial \varepsilon_{eq}} = 0 \tag{1}$$

where P is the internal pressure and \mathcal{E}_{eq} is the equivalent strain. For more detailed analyses and predictions regarding BP, refer to the works of Leis and Stephens [99], Bjørnøy et al. [100], Shuai [101], and Ma et al. [102]. The Pluvinage et al. [93] equation for pipeline BPL defines the use of linear and nonlinear analysis to justify the plasticity of material instability. The deep neural network utilised by Oh et al. [103] adopted a dented O&G pipeline, possibly across all API 5L X42-X120 grade carbon steel pipelines for BPL testing and prediction. The Oh et al. [103] method is an advanced technological approach that could validate the TNT explosive tradi-

tional approach of Song et al. [74]. Yan et al. [104] evaluated different BPL predictive models' errors and ascertained that the API RP579 and R6 are more efficient than the Battelle Model concept in O&G pipelines' BPL prediction. However, no specific certified reliable method exists for accurately forecasting BP strength, according to Bhardwaj et al. [79]. The Bhardwaj et al. [79] study further concludes that data collection also modelled a fullsized pipeline with respect to the geometry mirroring the initial quarter section of the pipe as proposed. The mesh sensitivity study of corroded pipe by Qin et al. [17] ascertains that a pipeline can still be in operation even at a corroded level. The level of corrosion is, therefore, a medium to justify the pipe stability in operation. The anodic current density initiated the corrosion defect on the pipeline at a different pressure flow rate, while other parameters like internal and external stress were introduced [17,70]. The Askari et al. [70] study is a proof and an example of the different types of internal corrosion that could happen in any hydrocarbon pipeline. The main factor of this internal corrosion in the pipelines is the sulphide content in hydrocarbons, which results in SSC.

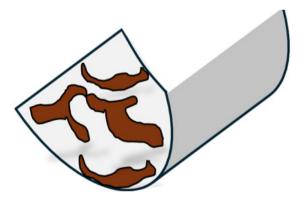

Figure 7. A half symmetry schematic of internal corroded hydrocarbon pipeline.

The damage incidents discussed herein do not indicate any failure propensity related to the design or installation process, but ageing within a steadily operated pipeline. Corrosion is the most significant factor in this context. Clogging is another notable contributor to the corrosion effect in onshore and offshore O&G pipelines, often resulting from dirt or other factors. Clogging in a pipeline increases the Maximum Operating Pressure (MOP) needed to transport the pipeline's content,

which may lead to higher operating costs and reduce BP. However, following pigging operations to mitigate the clogging, the flow resistance encountered by low-molecular-weight gas or liquid hydrocarbons can be alleviated, allowing for a potentially faster flow rate. Zhu et al. [105] employed fluid oscillation theory with mathematical models to detect clogs in pipelines, using plugging attenuation parameters to assess the specific location and volume of the blockage. Chern-Tong and Aziz [106] provided an example of a hydrocarbon product that causes coagulation due to low temperatures, which contributes to clogging in oil pipelines, ultimately leading to corrosive impacts on the pipeline. Additionally, hydrate formation in natural gas pipelines can also result in clogging, as Al-Sharify et al. [107] mildly put it.

Crack initiation in carbon steel pipelines often results from mechanical or stress impacts and can propagate when exposed to external loads. Additionally, dents may develop in high-grade carbon steel due to mechanical impact, before and after installation. Zhen et al. [64] evaluated the benefits of material thickness in X65 steel pipeline crack tip openings using a 3D FE model. The thicker the pipeline material, the greater its resistance to crack opening. A high-grade carbon steel, ranging from X42 to X80, falls within Product Specification Levels 1 and 2 (PSL1 and PSL2). It is, therefore, significant to note that butt-weld areas in pipelines are particularly vulnerable to stress corrosion cracking (SCC), which poses a high risk by potentially reducing the BP strength. Such weaknesses could lead to catastrophic incidents, including explosions, within the operational phase of a pipeline.

In another campaign to mitigate corrosion effects, Race [22] and Adib-Ramezani et al. [108] have drawn attention to corrosion management and control in onshore pipelines. This problem remains a global metal infrastructural challenge. In the same light, Dao et al. [109] study provides a valid analytical investigation of internal corrosion as a primary mode of subsea pipeline failure.

4.4.Structural-Empirical Based Analysis of **Pipelines with Defects**

tion that restricting laboratory carbon steel X-grade samples can effectively limit the prediction of crack and fracture behaviour in operational pipelines. Many of the articles evaluated by Zhen et al. [64] adopt a similar approach to those by Shterenlikht et al. [110], Amara et al. [111], and Shibanuma et al. [112] for studying the effects of cracks in pipelines. However, the use of laboratory specimens is insufficient for accurately assessing crack-related fractures in long and large O&G pipelines [111,112]. Consequently, the trend towards incorporating numerical and computational analysis to predict fracture and crack responses in natural gas pipelines appears to be the most effective strategy. It is essential to recognise that environmental factors play a significant role in many types of pipeline damage, including embrittlement, fractures, and cracks.

4.5.Empirical and Numerical Synthesis of **Damaged Pipelines**

Empirical and numerical methods for repairing and rehabilitating onshore and offshore O&G pipelines used for transportation have consistently shown reliable results through field investigations and computational validation. However, the welding of damaged sections of the pipeline has remained uncertain throughout the remaining pipeline's operational life. This uncertainty arises from differences in material properties, including the welding rod, the pipeline material itself, and the repair sleeve used.

5. Different Approaches for Flawed and Unflawed Pipeline Structural Analysis

The critically reviewed articles in this study examine both flawed and unflawed pipelines. They utilise a diverse range of methodologies rooted in analytical, semi-empirical, empirical, and numerical approaches to highlight the implications of defects and provide guidance for predicting failures. A newly commissioned pipeline, whether onshore or offshore, is expected to function effectively throughout its lifecycle. However, Zhen et al. [64] have strongly argued against the no- these expectations for pipeline performance and integrity can often be compromised by various challenges associated with the pipeline. To improve our understanding of different methods for analysing pipeline defects, a summary of several experimental, analytical, and computational tools is provided in **Tables 1–4**.

5.1. Pipeline Repair and Rehabilitation

FEM plays a critical role in assessing damaged pipelines, evaluating repair techniques, and ensuring the integrity of repaired sections. Case studies demonstrate the effectiveness of FEM-based simulations in guiding repair procedures, such as hot tapping, composite repairs, and pipeline replacements. The advanced welding technology for shipbuilding applications highlighted by Wahidi et al. [113] could serve as an adequate alternative for pipeline butt welding. Particularly in pipe joining, reeling, or construction on the badge ship before installation in the offshore environment. Additionally, quality joint welding and repair in pipelines are crucial because these processes are often prone to internal failures after repair. The harsh marine environmental conditions have made subsea pipelines challenging and problematic to repair and rehabilitate.

5.2. Pipeline Monitoring and Maintenance

A monitoring and maintenance programme for marine infrastructure is essential for ensuring efficiency and stability. It is the architectural hallmark of operational integrity in the harsh marine environment. Subsea O&G pipelines are no exception to this necessity. Therefore, constant routine monitoring and maintenance are crucial for transmission pipelines and are significant concerns for the O&G sector. Ho et al. [114] reviewed various articles focusing on the monitoring-inspection of O&G subsea pipelines. Most of these articles debated the best methodologies and technologies for inspecting and monitoring offshore pipelines. Among them are the corrosion-appraised articles in **Table 2**. Evans and Thomas [115] employed the Guided Wave Testing (GWT) principle to inspect corrosion in a straight offshore pipeline. GWT is a non-destructive testing (NDT) approach that uses wave propagation to locate and evaluate the corrosion potential of a pipeline. Dey

et al. ^[72] developed a unique risk-based model called the Analytic Hierarchy Process, designed to monitor and inspect pipelines. However, while pipeline monitoring is not always cost-effective, it is an unavoidable practice to prevent the loss of crude oil or natural gas due to leaks ^[72]. Witek ^[29] introduces a mathematical formulation by incorporating fibre-reinforced composites to repair corroded O&G pipelines, thereby preventing BP damage in both onshore and offshore pipelines. The MAOP, SOP, and MOP established by the design engineer are critical considerations in pipeline operations. Design standards, operational safety, and standard repair procedures for corroded pipelines are paramount for a pipeline's optimal function ^[1,29].

The analytical solution for the maximum theoretical failure pressure of the composite sleeve is given as **Equation (2)**:

$$P_{ ext{max}}^{ ext{th}} = rac{f_u(r_0 - r_i)}{lpha_{ heta}(r_i - \eta r_0)}$$
 (2)

where P_{max}^{th} is the maximum theoretical failure pressure, r_o is the outside radius of pipe, r_i is the inner radius of pipe, α_{θ} is the hoop stress, η is the coefficient of the pipe Young's modulus, and f_u is the Ultimate Tensile Strength (UTS) of the pipe. The hoop stress (α_{θ}) can be calculated as **Equation (3)**:

$$\alpha_{\theta} = \frac{1 - \left(\frac{d}{t}\right)\left(\frac{1}{Q}\right)}{1 - \left(\frac{d}{t}\right)} \tag{3}$$

where d d is the defect depth, t t is the pipe thickness, which is the difference between the outside and inner radius, $\frac{d}{t}$ is the defect depth to thickness ratio in %, and QQ is the bulging factor as it is used in the BG/DNV level 1 criterion. The coefficient the pipe Young's modulus is defined as **Equation (4)**:

$$\eta = \left(rac{r_0^2 E_{ ext{pipe}}(r_o - r_i)}{r_i^2 E_{ ext{sleeve}}(r_e - r_o)} + rac{r_o}{r_i}
ight)^{-1}$$
 (4)

where E_{pipe} is Young's modulus of pipe, E_{sleeve} is Young's modulus of sleeve, and r_e is the radius of the sleeve. The bulging factor can be calculated as **Equation (5)**:

$$Q = \sqrt{1 + 0.31 \left(\frac{L^2}{Dt}\right)} \tag{5}$$

sleeve pipe outside diameter, and tt is the sleeve pipe nominal thickness in (mm).

6. Conclusion

Remote and real-time monitoring, along with defect data analysis for BPL prediction, are key to enhancing pipeline operational effectiveness, efficiency, and integrity. In conclusion, this review study offers a comprehensive and high-quality systematic analysis from significant literature resources on both onshore and offshore pipelines. The main objectives outlined in the reviewed articles are pipeline operational capacity expectations depending on the operational environment, as presented by the cited authors. However, these objectives become compromised in the presence of pipeline defects. Addressing this problem, Tables 1-4 present additional structural defect mechanisms and predictive model reviews to reduce failure frequency and enhance pipeline flow efficiency.

The literature review employs a detailed and comprehensive systematic approach to unravel the application of the experimental, numerical, and analytical models presented in the appraised articles on structural defects. Notably, some of the numerical models assessed include robust FEM applications, which help to identify structural parameters for predicting failure modes in pipeline systems. Again, FEM stands as a foundational backbone of modern engineering design and analysis of onshore and offshore pipelines. The reviewed literature publications in this study have explored the myriad applications of FEM, ranging from modelling techniques and material considerations to environmental loading, failure modes, and case studies. Furthermore, most reviewed articles here ascertained that structural health failure from BP is not often sudden but initiated by one damage mode or the other and coupled with loss of operating pressure. A routine maintenance culture and proper checks while the pipeline is in operation are paramount to safety adherence, accentuation, and streamlining the control of mechanical problems to improve the pipeline's integrity [5].

Again, pipeline Bayesian model network assess-

where L is the defect length in (mm), DD is the ment for failure or integrity purposes has proven to be the best choice for risk and integrity evaluation of operational pipelines. As technology advances and challenges evolve, continued research and innovation in FEM will be crucial for ensuring the safety, reliability, and sustainability of pipeline systems. All these environmental and operational factors conjoined to cause immense loading conditions on the O&G pipelines. As offshore exploration ventures into deeper waters and harsher environments, the challenges faced by subsea pipeline engineers continue to evolve. The ability to model nonlinear material behaviour, dynamic environmental loading, and complex interaction phenomena allows engineers to make informed decisions throughout the lifecycle of subsea pipelines. It goes from the design and construction stage to the operation phase, maintenance, and decommissioning stage. Furthermore, the integration of FEM with data analytics, ML, and digital twins presents exciting opportunities for predictive maintenance, real-time monitoring, and risk management strategies.
